Preface

In 2019 we had a great opportunity to organize the 22nd edition of the International Conference on Business Information Systems (BIS 2019), that has grown to be a well-renowned event for scientific and business communities. This year the main topic of the conference was “Data Science for Business Information Systems.” The conference was jointly organized by the University of Seville, Spain, and the Poznań University of Economics and Business, Poland, and was held in Seville, Spain.

During each edition of the BIS conference series we make the effort to provide an opportunity for discussion about up-to-date topics from the area of information systems research. However, there are many topics that deserve particular attention. Thus, a number of workshops and accompanying events are co-located with the BIS conference series. The workshops give researchers the possibility to share preliminary ideas and initial experimental results, and to discuss research hypotheses from a specific area of interest.

Nine workshops and one accompanying event took place during BIS 2019. We were pleased to host well-known workshops such as AKTB (11th edition), BITA (10th edition), iCRM (4th edition), and iDEATE (4th edition), as well as relatively new initiatives such as ISAMD, DigEx, BSCT, SciBOWater, and QOD. Each workshop focused on a different topic: knowledge-based business information systems (AKTB), challenges and current state of business and IT alignment (BITA), integrated social CRM (iCRM), Big Data and business analytics ecosystems (iDEATE), Blockchain (BSCT), digital customer experience (DigEx), maritime systems (ISAMD), water management (SciBOWater), and data quality (QOD).

Additionally, BIS 2019 hosted a Doctoral Consortium. It was organized in a workshop format, thus the best papers from this event are included in this book. Moreover, all authors had the possibility to discuss their ideas on PhD thesis and research work with a designated mentor.

The workshop authors had the chance to present their results and ideas in front of a well-focused audience; thus the discussion gave the authors new perspectives and directions for further research. Based on the feedback received, authors had the opportunity to update their workshop articles for the current publication. This volume contains **57** articles that are extended versions of papers accepted for BIS workshops. In total, there were 139 submissions for all mentioned events. Based on the reviews, the respective workshop chairs accepted **57** in total, yielding an acceptance rate of **41%**.

We would like to express our thanks to everyone who made BIS 2019 workshops successful. First of all, our workshops chairs, members of the workshop Program

Committees, authors of submitted papers, and finally all workshops participants. We cordially invite you to visit the BIS website at <https://bisconf.org/> and to join us at future BIS conferences.

Abstract. We construct the Google matrices of bitcoin transactions for all year quarters during the period of January 11, 2009 till April 10, 2013. During the last quarters the network size contains about 6 million users (nodes) with about 150 million transactions. From PageRank and CheiRank probabilities, analogous to trade import and export, we determine the dimensionless trade balance of each user and model the contagion propagation on the network assuming that a user goes bankrupt if its balance exceeds a certain dimensionless threshold κ . We find that the phase transition takes place for $\kappa < \kappa_c \approx 0.1$ with almost all users going bankrupt. For $\kappa > 0.55$ almost all users remain safe. We find that even on a distance from the critical threshold κ_c the top PageRank and CheiRank users, as a house of cards, rapidly drop to the bankruptcy. We attribute this effect to strong interconnections between these top users which we determine with the reduced Google matrix algorithm. This algorithm allows to establish efficiently the direct and indirect interactions between top PageRank users. We argue that this study models the contagion on real financial networks.

Keywords: Markov chains · Google matrix · Financial networks

1 Introduction

The financial crisis of 2007–2008 produced an enormous impact on financial, social and political levels for many world countries (see e.g. [1, 2]). After this crisis the importance of contagion in financial networks gained a practical importance and generated serious academic research with various models proposed for the description of this phenomenon (see e.g. Reviews [3, 4]). The interbank contagion is of especial interest due to possible vulnerability of banks during periods of crisis (see e.g. [5, 6]). The bank networks have relatively small size with about $N \approx 6000$ bank units (nodes) for the whole US Federal Reserve [7] and about $N \approx 2000$ for bank units of Germany [8]. However, the access to these bank networks is highly protected that makes essentially forbidden any academic research of real bank networks.

However, at present the transactions in cryptocurrency are open to public and the analysis of the related networks are accessible for academic research. The first cryptocurrency is bitcoin launched in 2008 [9]. The first steps in the network analysis of bitcoin transactions are reported in [10, 11] and overview of bitcoin system development is given in [12]. The Google matrix analysis of the bitcoin network (BCN) has been pushed forward in [13] demonstrating that the main part of wealth of the network is captured by a small fraction of users. The Google matrix G describes the Markov transitions on directed networks and is at the foundations of Google search engine [14, 15]. It finds also useful applications for variety of directed networks described in [16]. The ranking of network nodes is based on the PageRank and CheiRank probabilities of G matrix which are on average proportional to the number of ingoing and outgoing links being similar to import and export in the world trade network [17, 18]. We use these probabilities to determine the balance of each user (node) of bitcoin network and model the contagion of users using the real data of bitcoin transactions from January 11, 2009 till April 10, 2013. We also analyze the direct and hidden (indirect) links between top PageRank users of BCN using the recently developed reduced Google matrix (REGOMAX) algorithm [19–23].

Table 1. List of Bitcoin transfer networks. The $BC_{yy}Qq$ Bitcoin network corresponds to transactions between active users during the q th quarter of year $20yy$. N is the number of users and N_l is the total amount of transactions in the corresponding quarter.

Network	N	N_l	Network	N	N_l	Network	N	N_l
BC10Q3	37818	57437	BC11Q3	1546877	2857232	BC12Q3	3742174	8381654
BC10Q4	70987	111015	BC11Q4	1884918	3635927	BC12Q4	4671604	11258315
BC11Q1	204398	333268	BC12Q1	2186107	4395611	BC13Q1	5997717	15205087
BC11Q2	696948	1328505	BC12Q2	2645039	5655802	BC13Q2	6297009	16056427

2 Datasets, Algorithms and Methods

We use the bitcoin transaction data described in [13]. However, there the network was constructed from the transactions performed from the very beginning till a given moment of time (bounded by April 2013). Instead, here we construct the network only for time slices formed by quarters of calendar year. Thus we obtain 12 networks with N users and N_l directed links for each quarter given in Table 1. We present our main results for BC13Q1.

The Google matrix G of BCN is constructed in the standard way as it is described in detail in [13]. Thus all bitcoin transactions from a given user (node) to other users are normalized to unity, the columns of dangling nodes with zero transactions are replaced by a column with all elements being $1/N$. This forms S matrix of Markov transitions which is multiplied by the damping factor $\alpha = 0.85$ so that finally $G = \alpha S + (1 - \alpha)E/N$ where the matrix E has all elements being unity. We also construct the matrix G^* for the inverted direction

of transactions and then following the above procedure for G . The PageRank vector P is the right eigenvector of G , $GP = \lambda P$, with the largest eigenvalue $\lambda = 1$ ($\sum_j P(j) = 1$). Each component P_u with $u \in \{u_1, u_2, \dots, u_N\}$ is positive and gives the probability to find a random surfer at the given node u (user u). In a similar way the CheiRank vector P^* is defined as the right eigenvector of G^* with eigenvalue $\lambda^* = 1$, i.e., $G^*P^* = P^*$. Each component P_u^* of P^* gives the CheiRank probability to find a random surfer on the given node u (user u) of the network with inverted direction of links (see [16, 24]). We order all users $\{u_1, u_2, \dots, u_N\}$ by decreasing PageRank probability P_u . We define the PageRank index K such as we assign $K = 1$ to user u with the maximal P_u , then we assign $K = 2$ to the user with the second most important PageRank probability, and so on ..., we assign $K = N$ to the user with the lowest PageRank probability. Similarly we define the CheiRank indexes $K^* = 1, 2, \dots, N$ using CheiRank probabilities $\{P_{u_1}^*, P_{u_2}^*, \dots, P_{u_N}^*\}$. $K^* = 1$ ($K^* = N$) is assigned to user with the maximal (minimal) CheiRank probability.

The reduced Google matrix G_R is constructed for a selected subset of N_r nodes. The construction is based on methods of scattering theory used in different fields including mesoscopic and nuclear physics, and quantum chaos. It describes, in a matrix of size $N_r \times N_r$, the full contribution of direct and indirect pathways, happening in the global network of N nodes, between N_r selected nodes of interest. The PageRank probabilities of the N_r nodes are the same as for the global network with N nodes, up to a constant factor taking into account that the sum of PageRank probabilities over N_r nodes is unity. The (i, j) -element of G_R can be viewed as the probability for a random seller (surfer) starting at node j to arrive in node i using direct and indirect interactions. Indirect interactions describes pathways composed in part of nodes different from the N_r ones of interest. The computation steps of G_R offer a decomposition into matrices that clearly distinguish direct from indirect interactions, $G_R = G_{tr} + G_{pr} + G_{qr}$ [20]. Here G_{tr} is generated by the direct links between selected N_r nodes in the global G matrix with N nodes. The matrix G_{pr} is usually rather close to the matrix in which each column is given by the PageRank vector P_r . Due to that G_{pr} does not bring much information about direct and indirect links between selected nodes. The interesting role is played by G_{qr} . It takes into account all indirect links between selected nodes appearing due to multiple pathways via the N global network nodes (see [19, 20]). The matrix $G_{qr} = G_{qrd} + G_{qrnd}$ has diagonal (G_{qrd}) and non-diagonal (G_{qrnd}) parts where G_{qrnd} describes indirect interactions between nodes. The explicit mathematical formulas and numerical computation methods of all three matrix components of G_R are given in [19, 20, 22, 23].

Following [18, 22, 23], we remind that the PageRank (CheiRank) probability of a user u is related to its ability to buy (sell) bitcoins, we therefore determine the balance of a given user as $B_u = (P^*(u) - P(u)) / (P^*(u) + P(u))$. We consider that a user u goes to bankruptcy if $B_u \leq -\kappa$. If it is the case the user u ingoing flow of bitcoins is stopped. This is analogous to the world trade case when countries with unbalanced trade stop their import in case of crisis [17, 18]. Here

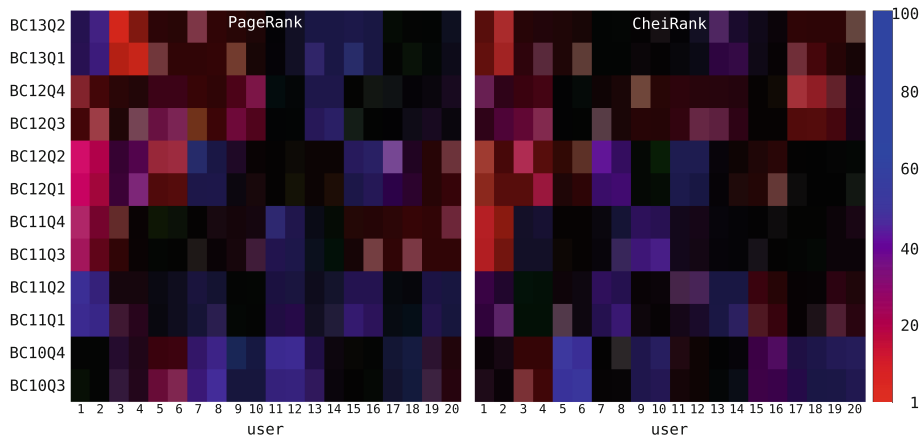

Fig. 1. Twenty most present users in top100s of BCyyQq networks (see Table 1) computed with PageRank (left panel) and CheiRank (right panel) algorithms. In horizontal axis the twenty users labeled from 1 to 20 are ranked according to the number of occurrences in the time slice top100s. The color ranges from red (user is ranked at the 1st position, $K = 1$ or $K^* = 1$) to blue (user is ranked at the 100th position, $K = 100$ or $K^* = 100$). Black color indicates a user absent from the top100 of the corresponding time slice. (Color figure online)

κ has the meaning of bankruptcy or crisis threshold. Thus the contagion model is defined as follows: at iteration τ , the PageRank and CheiRank probabilities are computed taking into account that all ingoing bitcoin transactions to users went to bankruptcy at previous iterations are stopped (i.e., these transactions are set to zero). Using these new PageRank and CheiRank probabilities we compute again the balance of each user, determining which additional users went to bankruptcy at iteration τ . Initially at the first iteration, $\tau = 1$, PageRank and CheiRank probabilities and thus user balances are computed using the Google matrices G and G^* constructed from the global network of bitcoin transactions (*a priori* no bankrupted users). A user who went bankrupt remains in bankruptcy at all future iterations. In this way we obtain the fraction, $W_c(\tau) = N_u(\tau)/N$, of users in bankruptcy or in crisis at different iteration times τ .

3 Results

The PageRank and CheiRank algorithms have been applied to the bitcoin networks BCyyQq presented in Table 1. An illustration showing the rank of the twenty most present users in the top 100s of these bitcoin networks is given in Fig. 1. We observe that the most present user (#1 in Fig. 1) was, from the third quarter of 2011 to the fourth quarter of 2012, at the very top positions of both the PageRank ranking and of the CheiRank ranking. Consequently, this user was very central in the corresponding bitcoin networks with a very influential activity of bitcoin seller and buyer. Excepting the case of the most present user (#1

in Fig. 1), the other users are (depending of the year quarter considered) either top sellers (well ranked according to CheiRank algorithm, $K^* \sim 1 - 100$) or top buyers of bitcoins (well ranked according to PageRank algorithm, $K \sim 1 - 100$). In other words excepting the first column associated to user #1 there is almost no overlap between left and right panels of Fig. 1.

From now on we concentrate our study on the BC13Q1 network. For this bitcoin network, the density of users on the PageRank-CheiRank plane (K, K^*) is shown in Fig. 2a. At low K, K^* , users are centered near the diagonal $K = K^*$ that corresponds to the fact that on average users try to keep balance between ingoing and outgoing bitcoin flows. Similar effect has been seen also for world trade networks [17].

The dependence of the fraction of bankrupt users $W_c = N_u/N$ on the bankruptcy threshold κ is shown in Fig. 2b at different iterations τ . At low $\kappa < \kappa_c \approx 0.1$ almost 100% of users went bankrupt at large $\tau = 10$.

Fig. 2. Panel a: density of users, $dN(K, K^*)/dKdK^*$, in PageRank-CheiRank plane (K, K^*) for BC13Q1 network; density is computed with 200×200 cells equidistant in logarithmic scale; the colors are associated to the decimal logarithm of the density; the color palette is a linear gradient from green color (low user densities) to red color (high user densities). Black color indicates absence of users. Panel b: fraction N_u/N of BC13Q1 users in bankruptcy shown as a function of κ for $\tau = 1, 3, 5$, and 10.

Indeed, Fig. 3 shows that the transition to bankruptcy is similar to a phase transition so that at large τ we have $W_c = N_u/N \approx 1$ for $\kappa < \kappa_c \approx 0.1$, in the range $\kappa_c \approx 0.1 < \kappa < 0.55$ there are only about 50%–70% of users in bankruptcy while for $\kappa > 0.55$ almost all users remain safe at large times.

The distribution of bankrupt and safe users on PageRank-CheiRank plane (K, K^*) is shown in Fig. 4 at different iteration times τ . For crisis thresholds $\kappa = 0.15$ and $\kappa = 0.3$, we see that very quickly users at top $K, K^* \sim 1$ indexes go bankrupt and with growth of τ more and more users go bankrupt even if they

Fig. 3. Fraction N_u/N of BC13Q1 users in bankruptcy as a function of κ and τ . (Color figure online)

are located below the diagonal $K = K^*$ thus having initially positive balance B_u . However, the links with other users lead to propagation of contagion so that even below the diagonal many users turn to bankruptcy. This features are similar for $\kappa = 0.15$ and $\kappa = 0.3$ but of course the number of safe users is larger for $\kappa = 0.3$. For a crisis threshold $\kappa = 0.6$, the picture is stable at every iterations τ , the contagion is very moderate and concerns only the white region comprising roughly the same number of safe and bankrupt users. This white region broadens moderately as τ increases. We note that even some of the users above $K = K^*$ remain safe. We observe also that for $\kappa = 0.6$ about a third of top $K, K^* \sim 1$ users remain safe.

Figure 5 presents the integrated fraction, $W_c(K) = N_u(K)/N$, of users which have a PageRank index below or equal to K and which went bankrupt at $\tau \leq 10$. We define in a similar manner the integrated fraction of CheiRank users $W_c(K^*) = N_u(K^*)/N$ being bankrupts. From Fig. 5 we observe $W(K) \approx K/N$ and $W(K^*) \approx K^*/N$. Formal fits $W_c(K) = \mu^{-1}K^\beta$ of the data in the range

Fig. 4. BC13Q1 users in bankruptcy (red) and safe (blue) for $\kappa = 0.15$ (top row), for $\kappa = 0.3$ (middle row), and for $\kappa = 0.6$ (bottom row). For each panel the horizontal (vertical) axis corresponds to PageRank (CheiRank) indexes K (K^*). In logarithmic scale, the (K, K^*) plane has been divided in 200×200 cells. Defining N_{cell} as the total number of users in a given cell and $N_{u,\text{cell}}$ as the number of users who went bankrupt in the cell until iteration τ , we compute, for each cell, the value $(2N_{u,\text{cell}} - N_{\text{cell}})/N_{\text{cell}}$ giving +1 if every user in the cell went bankrupt (dark red), 0 if the number of users went bankrupt is equal to the number of safe users, and -1 if no user went bankrupt (dark blue). Black colored cells indicate cell without any user. (Color figure online)

$10 < K < 10^5$ give $(\mu = 5.94557 \times 10^6 \pm 95, \beta = 0.998227 \pm 1 \times 10^{-6})$ for $\kappa = 0.15$ and $(\mu = 5.65515 \times 10^6 \pm 231, \beta = 0.99002 \pm 4 \times 10^{-6})$ for $\kappa = 0.3$. Formal fits $W_c(K^*) = \mu^{-1} K^{*\beta}$ of the data in the range $10 < K^* < 10^5$ give $(\mu = 1.03165 \times 10^7 \pm 3956, \beta = 1.02511 \pm 3 \times 10^{-5})$ for $\kappa = 0.15$ and $(\mu = 1.67775 \times 10^7 \pm 1.139 \times 10^4, \beta = 1.05084 \pm 6 \times 10^{-5})$ for $\kappa = 0.3$.

The results of contagion modeling show that PageRank and CheiRank top users $K, K^* \sim 1$ enter in contagion phase very rapidly. We suppose that this happens due to strong interlinks existing between these users. Thus it is interesting to see what are the effective links and interactions between these top PageRank

Fig. 5. Integrated fractions, $W_c(K)$ and $W_c(K^*)$, of BC13Q1 users which went bankrupt at $\tau \leq 10$ for $\kappa = 0.15$ (solid lines) and for $\kappa = 0.3$ (dashed lines) as a function of PageRank index K (black lines) and CheiRank index K^* (red lines). The inset shows $W_c(K)N/K$ as a function of K and $W_c(K^*)N/K^*$ as a function of K^* . (Color figure online)

and top CheiRank users. With this aim we construct the reduced Google matrix G_R for the top 20 PageRank users of BC13Q1 network. This matrix G_R and its three components G_{PR} , G_{TR} and G_{QRnd} are shown in Fig. 6. We characterize each matrix component by its weight defined as the sum of all matrix elements divided by $N_r = 20$. By definition the weight of G_R is $W_R = 1$. The weights of all components are given in the caption of Fig. 6. We see that W_{PR} has the weight of about 50% while W_{TR} and W_{QR} have the weight of about 25%. These values are significantly higher comparing to the cases of Wikipedia networks (see e.g. [20]). The G_{TR} matrix component (Fig. 6 bottom left panel) is similar to the bitcoin mass transfer matrix [13] and the (i, j) -element of G_{TR} is related to direct

Fig. 6. Reduced Google matrix G_R associated to the top 20 PageRank users of BC13Q1 network. The reduced Google matrix G_R (top left) has a weight $W_R = 1$, its components G_{rr} (bottom left), G_{pr} (top right), and G_{qrnd} (bottom right) have weights $W_{rr} = 0.29339$, $W_{pr} = 0.48193$, and $W_{qr} = 0.22468$ ($W_{qrnd} = 0.11095$). Matrix entries are ordered according to BC13Q1 top 20 PageRank index.

bitcoin transfer from user j to user i . As $W_{rr} = 0.29339$, the PageRank top20 users directly transfer among them on average about 30% of the total of bitcoins exchanged by these 20 users. In particular, about 70% of the bitcoin transfers from users $K = 5$ and $K = 14$ are directed toward user $K = 2$. Also user $K = 5$ buy about 30% of the bitcoins sold by user $K = 2$. We observe a closed loop between users $K = 2$ and $K = 5$ which highlights between them an active bitcoin trade during the period 2013 Q1. Also 30% of bitcoins transferred from user $K = 19$ were bought by user $K = 1$. The 20×20 reduced Google matrix G_R (Fig. 6 top left panel) gives a synthetic picture of bitcoin direct and indirect transactions taking into account direct transactions between the $N \sim 10^6$ users encoded in the global $N \times N$ Google matrix G . We clearly see that many bitcoin transfers converge toward user $K = 1$ since this user is the most central in the

bitcoin network. Although the G_{rr} matrix component indicates that user $K = 1$ obtains about 10% to 30% of the bitcoins transferred from its direct partners, the G_{dr} matrix component indicates that indirectly the effective amount transferred from direct and indirect partners are greater about 10% to more than 45%. In particular, although no direct transfer exists from users $K = 11$ and $K = 16$ to user $K = 1$, about 45% of the bitcoins transferred in the network from users $K = 11$ and $K = 16$ converge indirectly to user $K = 1$. Looking at the diagonal of the G_R matrix we observe that about 60% of the transferred bitcoins from user $K = 1$ returns effectively to user $K = 1$, the same happen, e.g, with user $K = 2$ and user $K = 15$ with about 30% of transferred bitcoins going back. The G_{qr} matrix component (Fig. 6 bottom right panel) gives the interesting picture of hidden bitcoin transactions, i.e., transactions which are not encoded in the G_{rr} matrix component since they are not direct transactions, and which are not captured by the G_{dr} matrix component as they do not necessarily involve transaction paths with the most central users. Here we clearly observe that 25% of the total transferred bitcoins from user $K = 15$ converge indirectly toward user $K = 2$. We note that this indirect transfer is the result of many indirect transaction pathways involving many users other than the PageRank top20 users. We observe also a closed loop of hidden transactions between users $K = 17$ and $K = 18$.

4 Discussion

We performed the Google matrix analysis of Bitcoin networks for transactions from the very start of bitcoins till April 10, 2013. The transactions are divided by year quarters and the Google matrix is constructed for each quarter. We present the results for the first quarter of 2013 being typical for other quarters of 2011, 2012. We determine the PageRank and CheiRank vectors of the Google matrices of direct and inverted bitcoin flows. These probabilities characterize import (PageRank) and export (CheiRank) exchange flows for each user (node) of the network. In this way we obtain the dimensionless balance of each user B_u ($-1 < B_u < 1$) and model the contagion propagation on the network assuming that a user goes bankrupt if its dimensional balance exceeds a certain bankruptcy threshold κ ($B_u \leq -\kappa$). We find that the phase transition takes place in a vicinity of the critical threshold $\kappa = \kappa_c \approx 0.1$ below which almost 100% of users become bankrupts. For $\kappa > 0.55$ almost all users remain safe and for $0.1 < \kappa < 0.55$ about 60% of users go bankrupt. It is interesting that, as house of cards, the almost all top PageRank and Cheirank users rapidly drop to bankruptcy even for $\kappa = 0.3$ being not very close to the critical threshold $\kappa_c \approx 0.1$. We attribute this effect to strong interconnectivity between top users that makes them very vulnerable. Using the reduced Google matrix algorithm we determine the effective direct and indirect interactions between the top 20 PageRank users that shows their preferable interlinks including the long pathways via the global network of almost 6 million size.

We argue that the obtained results model the real situation of contagion propagation of the financial and interbank networks.
